Abstract

We examined the efficacy of combination treatments utilizing cytotoxic drugs plus inhibitors to members of the ErbB - ERK signal pathway in human prostate cancer (PCa) LNCaP C-81 cells. Under an androgen-reduced condition, 50 nM gemcitabine caused about 40% growth suppression on C-81 cells. Simultaneous treatment of gemcitabine plus 10 µM AG825 produced 60% suppression (p<0.03); while, 85% growth inhibition (p<0.02) was seen if AG825 was added to gemcitabine-treated cells after a 24 hr-interval. Our data thus showed that in androgen-reduced conditions, inhibition of ErbB-2 increases the cytotoxic efficacy of gemcitabine in PCa cells. This finding has significant implications in the choice of drugs for combination therapy as well as the order of administration for treating cancer patients.

Keywords

Hormone-refractory prostate cancer; Gemcitabine; ErbB-2 Inhibitor; Combination therapy

1. Introduction

Prostate cancer (PCa) is the second leading cause of male cancer mortality in the United States of America [1]. Several approaches, including surgery and radiation therapies, provide
clinicians with effective options for treating patients with localized cancer; while androgen ablation therapy remains the main choice for treating metastatic disease [2]. However, patients with advanced PCa benefit only temporarily from androgen deprivation treatment, and the disease progresses to hormone-refractory cancer [2]. Progress in treating this stage of PCa has been very modest with only one chemotherapeutic agent – docetaxel - having demonstrated any meaningful benefit. It is imperative to explore new therapeutic regimens with less toxicity and higher efficacy.

Members of the ErbB family, including epidermal growth factor receptor (EGFR) and its ligands and ErbB-2/HER-2/Neu, are frequently elevated and/or mutation-activated in a variety of malignant diseases [3,4]. The activation of the mitogen-activated protein kinases (MAPKs) can also contribute to tumorigenesis. In PCa, ErbB to MAPK signal pathway is activated, correlating with hormone-refractory cancer progression [5–7]. The EGFR expression level is suggested to be associated with Gleason scores as well as the androgen-independent stage, and therefore the inhibition of EGFR signaling may suppress tumor angiogenesis [8]. ErbB-2 signaling also plays a critical role in PCa progression and correlates with hormone-refractory proliferation [9,10]. These observations lead to the hypothesis that targeting the ErbB members to MAPK signaling pathway could have therapeutic potential on those cancer cells. Thus, developing inhibitors toward those molecules has been actively pursued for improving the efficacy of cancer therapy.

The members of the Bcl-2 family represent critical check points within apoptotic pathways. Bcl-2 promotes cell survival by suppressing cellular apoptosis [11]. In PCa, up-regulation of Bcl-2 correlates with its progression to the advanced hormone-refractory stage and increases radiation resistance [11]. Conversely, pro-apoptotic Bax protein effectively antagonizes Bcl-2 action, thereby promoting apoptosis [12]. It appears that the ratio of anti-apoptotic proteins, e.g., Bcl-2 and Bcl-XL, to pro-apoptotic proteins, e.g., Bax and Bad, determines at least in part how cells will respond to apoptotic or survival signals [12]. To implement this approach in practice is to shift the ratio to favor apoptosis by decreasing anti-apoptotic and/or increasing pro-apoptotic gene expression [13].

Combining different classes of drugs has proven effective in treating various cancers since the drug resistance of cancers is likely due to the heterogeneity of cancer cell populations. Nevertheless, drug combinations tend to be more toxic to normal cells and patients are more susceptible to adverse side effects. A new strategy is thus critically needed. Inhibitors to protein tyrosine kinases (PTKs), including ErbB family members, have been shown to enhance the therapeutic efficacy of some conventional cytotoxic agents [7,14]. Combinations of MAP kinase/ERK kinase (MEK) inhibitors with docetaxel can increase cellular apoptosis in androgen-independent PCa cells under androgen-reduced conditions [7]. The same efficacy on cell growth suppression could be achieved by the combination treatment with a lower dose of cytotoxic agents plus inhibitors to signal transduction pathways, compared to combination therapies with conventional drugs.

Cancer treatment with DNA-damaging agents is commonly used in clinic. Gemcitabine (2’, 2’-difluoro-2’-deoxycytidine), an analog of deoxycytidine that inhibits DNA biosynthesis, exhibits effective anticancer activity toward several cancers [15]. It is also considered to be one of the most promising agents used in combination treatments [14,16]. Several clinical studies have analyzed the efficacy of combined treatments of gemcitabine plus other agents such as taxanes, vinorelbine, vindesine, cisplatin, 5-fluorouracil as well as anthracyclines across various regimens and conditions of pretreatment [17–19]. Most of those two-drug combination treatments have consistently demonstrated higher efficacy than either single agent. Importantly, recent studies reveal a potential synergistic effect by combination treatments with gemcitabine plus PTK inhibitors [20]. However, the efficacy of gemcitabine...
as a single agent or in combination utility for treating advanced PCa has yet to be fully investigated [21].

In this study, we investigated whether combination treatments could enhance the efficacy of gemcitabine for treating hormone-refractory PCa, utilizing androgen-independent human PCa LNCaP C-81 cells as the model system. These LNCaP C-81 cells exhibit many biochemical features observed in clinical hormone-refractory PCa [22–24]. These cells thus serve as a useful cell model in designing novel therapeutic approaches toward androgen receptor (AR)-positive, androgen-independent PCa, the major population of advanced PCa cells. We investigated if combination therapy of gemcitabine plus inhibitors to the ErbB signal pathway can reduce the effective dose of gemcitabine, alleviating its impact on normal cells and concurrently increasing its effect on growth suppression. To mimic clinical applications of chemotherapeutic agents during androgen ablation therapy of PCa, we examined the combination efficacy on suppressing LNCaP C-81 cells in an androgen-reduced condition.

2. Materials and methods

2.1. Materials

Fetal bovine serum (FBS), cell culture medium RPMI 1640 and gentamicin were purchased from Invitrogen Life Technologies (Carlsbad, CA). Specific antibodies (Abs) to Bcl-2 and Bax and horseradish peroxidase-conjugated anti-mouse and anti-rabbit IgG Abs were from Santa Cruz Biotechnology (Santa Cruz, CA). Charcoal/Dextran-treated, certified FBS was from HyClone (Logan, UT). Docetaxel and gemcitabine were obtained from the Nebraska Health System University Hospital. PD98059, AG825 and AG1478 were from Calbiochem (San Diego, CA). All other reagents were obtained as described in previous publications [7,9].

2.2. Cell culture

Human PCa cell line LNCaP was purchased from the American Type Culture Collection and routinely maintained in the regular culture medium, i.e., phenol red (PR)-containing RPMI 1640 medium supplemented with 5% (v/v) FBS, 2 mM glutamine and 50 µg/ml gentamicin [22,23]. LNCaP parental cells are androgen-sensitive and express prostate-specific antigen (PSA). Upon passage, LNCaP cells gradually lost androgen sensitivity. For experiments, LNCaP C-81 cells that had passage numbers between 80 and 120 and exhibited androgen-independent growth were used as the model system [22,23]. Despite the expression of functional AR in LNCaP C-81 cells, the growth of C-81 cells is androgen-independent. Furthermore, C-81 cells exhibit many biochemical characteristics as seen in advanced hormone-refractory PCa, for example, in the presence of castrated levels of androgens, those cells secrete PSA, exhibit rapid growth rates and high tumorigenicity in xenograft animals [22–24]. Importantly, these cells exhibit intracrine regulation by biosynthesizing testosterone from cholesterol as observed in some advanced PCa [25]. For determining cell growth, the total cell number was counted using a Coulter Counter Z1 model [9].

2.3. Treatment with chemotherapeutic agents

For experiments, cells were seeded in the regular medium for 2 days and then fed with a steroid-reduced (SR) medium, i.e., phenol-red (PR)-free RPMI 1640 medium containing 5% (v/v) heat-inactivated, charcoal/dextran-stripped fetal bovine serum (CS-FBS), 2 mM glutamine and 50 µg/ml gentamicin. After 2 days, cells were fed with fresh SR medium and treated with PD98059, AG825, AG1478, gemcitabine, or docetaxel, either alone or in combination, as specified in each experiment, for 3 days [7]. To quantify the cell growth, attached cells were trypsinized and cell number was counted with a Coulter Counter. All experiments were done in triplicates and repeated at least twice.
2.4. Western blotting

Briefly, cells were scraped, pelleted and rinsed with ice-cold HEPES-buffered saline, pH 7.0, and then lysed in an ice-cold cell lysis buffer containing a battery of protease and phosphatase inhibitors [22,26]. For immunoblotting, the nitrocellulose membrane filter was blocked and subsequently incubated with appropriate primary Ab. After rinsing, the filter was incubated with secondary Ab. The protein bands were visualized by an ECL detection system. For reblotting, filters were agitated with the stripping buffer for 30 min at 50°C [9,23].

2.5. TUNEL assay

A TUNEL assay Kit (Roche, Indianapolis, IN) was used to measure apoptosis [7]. Briefly, cells were plated on coverslips in regular culture medium for 48 hr and then in SR medium for an additional 48 hr. Cells were fed with fresh SR medium with or without reagents for 72 hr. The apoptotic cells were detected by the commercial kit, following the accompanying protocol. Apoptotic cells were observed under a light microscope and were counted in 5 randomly selected fields.

2.6. Data analysis

All western blot experiments were conducted at least twice and the most representative results were presented. The intensities of hybridization bands were semi-quantified by densitometric analyses of films with different exposure time periods, utilizing the BioRad Gel-Doc Gel Imager [7]. The statistical procedures for p-value analysis were performed by the student t-test with two populations to determine significance of comparisons. p<0.05 was considered as significant difference.

3. Results

We analyzed the growth suppression by combination treatments, utilizing cytotoxic agents plus inhibitors to PTKs in clinic-relevant, androgen-independent human PCa LNCaP C-81 cells. The utilization of C-81 cells is because these cells exhibit many biochemical properties as seen in hormone-refractory PCa, e.g., in the absence of androgen, these cells secret PSA and exhibit high tumorigenicity [22–24]. To mimic the clinical scenario in which androgen ablation is the first line of treatment for patients with metastatic PCa, all experiments were conducted in a steroid-reduced condition, in which phenol red-free medium was used because phenol red exhibits stimulatory activity on androgen-sensitive LNCaP cells [27] Initial results showed that both docetaxel and gemcitabine each inhibited the growth of LNCaP C-81 cells effectively, following a dose-response manner (Fig. 1A). Clinic-relevant doses of gemcitabine at 50 nM and of docetaxel at 2.4 nM alone inhibited the growth of C-81 cells by approximately 40% and 60%, respectively (Fig. 1A, upper panel). Furthermore, TUNEL assay analyses revealed that growth inhibition on LNCaP C-81 cells by docetaxel and gemcitabine was at least in part due to their effects on the apoptotic pathway (Fig. 1A, lower panel). We found that the limited efficacy of growth suppression by these two cytotoxic agents was at least in part due to their concurrent effects on increasing anti-apoptotic Bcl-2 and Bcl-XL protein levels (Fig. 1B).

We initially analyzed the efficacy of combination treatment with gemcitabine plus docetaxel. Unexpectedly, the concurrent treatment of both cytotoxic agents did not enhance growth inhibition. Only approximately 30% growth inhibition was observed with this combination, lower than either agent alone (Fig. 2, lane #6 vs. #2 &3). Because several studies have shown that the ErbB-2 – MAPK/ERK pathway is activated in PCa cells, especially in advanced hormone-refractory cancer cells [7,9,28], we examined growth suppression on C-81 cells by inhibitors to ErbB-2 and MEK, the up-stream of MAPK/ERK. Under androgen-reduced conditions, at 10 µM concentration each, both ErbB-2 inhibitor AG825 and MEK inhibitor PD098059 as single agents inhibited the growth of those cells only about 15% in a 3-day...
treatment (Fig. 2, lane #4&5). Unexpectedly, PD098059 abolished the cytotoxic effect of gemcitabine when both agents were administrated together (Fig. 2, lane #7). Nevertheless, the combination of AG825 with gemcitabine exhibited an added effect with approximately 60% growth suppression (p<0.03, lane #8 vs. #2). Interestingly, a synergistic effect with over 80% growth suppression was obtained when AG825 was added to the culture 24h after their exposure to gemcitabine (p<0.02, lane #9 vs. #2; p<0.05, #9 vs. #8). To rule out whether it is a cell line-specific phenomenon, we tested the combined AG825 and gemcitabine treatment on high passage MDA PCa2b cells, an AR-positive, androgen-independent PCa cells exhibiting similar biochemical properties to C-81 cells and hormone-refractory PCa [29]. Our data clearly showed that in the steroid-reduced condition, those cells also responded to the sequential, combined treatment as observed on LNCaP C-81 cells (data not shown). Thus, in androgen-reduced conditions, AG825, but not PD98059, can enhance the cytotoxic effect by gemcitabine and a sequential combination treatment resulted in even greater growth suppression on AR-positive, androgen-independent PCa cells, representing the majority of hormone-refractory PCa in clinic.

To determine whether gemcitabine plus AG825 inhibited LNCaP C-81 cell growth by enhancing the apoptotic pathway, we analyzed the expression of pro-apoptotic protein Bax and anti-apoptotic proteins Bcl-2 and Bcl-XL in those treated cells. As shown in Fig. 3 (lane #2), in 50 nM gemcitabine alone-treated C-81 cells, comparing with control cells (lane #1), Bax protein level was elevated by approximately 5-fold, while the Bcl-XL was also elevated by about 50% with only a minor increase of Bcl-2 protein level. Treatment with 2.4 nM docetaxel alone (Fig. 3, lane #3) resulted in an elevated Bax protein level by about 2-fold with slight elevation of Bcl-2 as well as Bcl-XL protein level. AG825 and PD98059, at 10 µM each, had only moderate effects on both pro- and anti-apoptotic proteins (lanes #4&5). When combined with gemcitabine, neither docetaxel (lane #6) nor PD98059 (lane #7) had a significant effect on decreasing anti-apoptotic protein levels nor enhancing pro-apoptotic protein levels in treated cells, comparing with gemcitabine alone-treated cells (Fig. 3, lane #2). Interestingly, when AG825 was added to gemcitabine, Bcl-2 and Bcl-XL protein levels were decreased; lower than that of gemcitabine alone-treated cells, with no significant change in Bax protein in those cells (Fig. 3, lane #8 vs. #2). Additionally, when AG825 was introduced to the cell cultures 24-hr after gemcitabine treatment, the Bax protein level was further elevated; while both Bcl-2 and Bcl-XL protein levels were further decreased. These results therefore provide with a mechanistic explanation that AG825-enhanced gemcitabine action on growth suppression in those cells.

We examined whether the inhibitor of EGFR could similarly enhance the susceptibility of C-81 cells to gemcitabine-induced apoptosis. C-81 cells were treated with the EGFR inhibitor AG1478 plus gemcitabine, compared with AG825 plus gemcitabine in a steroid-reduced condition. As shown in Fig. 4A, after a 72-hour treatment, 10 µM AG1478 exhibited approximately a 15% growth suppression, similar to AG825 (lane #3 vs. #2). The combination of 10 µM AG1478 plus 50 nM gemcitabine produced only approximately 30% growth suppression (Fig. 4A, lane #6). In the same set of experiments, 50 nM gemcitabine plus 10 µM AG825 achieved growth suppression by approximately 60% (Fig. 4A, lane #5). Thus, in a steroid-reduced condition, inhibition of EGFR could not enhance the efficacy of gemcitabine on C-81 cell growth suppression.

To elucidate further the molecular mechanisms of differential growth suppressions by gemcitabine plus AG825 vs. AG1478 on C-81 cells, we examined their effects on the expression levels of Bcl-2 and Bax proteins. In C-81 cells treated with either 50 nM gemcitabine (lane #4), 10 µM AG1478 (lane #3) or AG825 (lane #2) alone, the level of anti-apoptotic Bcl-2 protein was elevated, higher than that in control cells (Fig. 4B). Furthermore, AG825 abolished gemcitabine-induced increases of Bcl-2 protein level, resulting in expression levels even lower...
than in control cells (Fig. 4B, lane #5, Fig. 3, lane #8). Nevertheless, AG1478 enhanced gemcitabine-induced Bcl-2 protein level in those cells, compared with that in single agent-treated cells (Fig. 4B, lane #6). Additionally, treatment of C-81 cells with gemcitabine or AG825, but not AG1478, resulted in an elevated pro-apoptotic Bax protein level (Fig. 4B, lane #2 & 4). The increase of Bax protein level was further enhanced by the combination treatment of gemcitabine plus AG825, correlating with growth suppression (Fig. 4B, lane #5). Although co-administration of AG1478 with gemcitabine could increase Bax protein level, in those cells, anti-apoptotic proteins Bcl-2 (Fig. 4B, lane #6) and Bcl-XL (data not shown) were also greatly elevated. The data collectively provided a mechanistic explanation for the lack of enhanced efficacy of AG1478 in gemcitabine-induced apoptosis.

4. Discussion

The efficacy of chemotherapeutic regimens for treating advanced hormone-refractory PCa is limited [2,30–32]. The objective of this study is to investigate whether the combination of chemotherapeutic agents with PTK inhibitors can enhance the apoptotic pathway of androgen-independent human PCa cells in an androgen-reduced culture condition. We also elucidate the mechanism of improved efficacy as it relates to changes in apoptotic proteins.

We initially analyzed the effect of combination treatment of gemcitabine plus docetaxel. Each agent alone exhibits efficacy toward several cancers, and their combination treatments have shown promising results for treating advanced non-small cell lung cancer [33]. Our data revealed that simultaneous administration of gemcitabine and docetaxel does not have an added effect of growth suppression on androgen-independent PCa cells in an androgen-reduced condition (Fig 2). Unexpectedly, the efficacy of growth suppression was decreased. We found that adding docetaxel to gemcitabine decreases the amount of pro-apoptotic, Bax, compared with gemcitabine alone and failed to decrease the amounts of the anti-apoptotic proteins, Bcl-XL and Bcl-2 (Fig 3).

We analyzed whether inhibitors to ErbB family members could add to the growth suppression by gemcitabine, due to the importance of the ErbB family members in PCa progression [8,9,34] and hormone-refractory proliferation [9,10,35–37]. We also investigated whether the MEK inhibitor PD98059 could enhance gemcitabine efficacy because MAPK pathways are associated with prostate cell mitogenesis and androgen-ablation survival [28], and also because PD98059 can enhance docetaxel-induced apoptosis in androgen-independent PCa cells under steroid-reduced conditions [7]. Interestingly, only AG825, but not PD98059 or AG1478, could enhance the growth suppression induced by gemcitabine in AR-positive, androgen-independent PCa cells under a steroid-reduced condition. Our data thus support the notion that ErbB-2, but not EGFR, plays a critical role in the androgen-independent proliferation of those cells [9,22,35,36]. This observation that inhibition of EGFR activity in LNCaP C-81 cells does not enhance growth inhibition by gemcitabine is in parallel with the observations that inhibition of proliferation and induction of apoptosis is independent of EGFR activity in some other cancer cells [38,39]. Additionally, this combined treatment in steroid-reduced conditions should not have a profound effect on non-malignant prostate epithelia because they are androgen-sensitive cells and will not proliferate under this environment even in the absence of treatment.

Overexpression of Bcl-2 correlates with progression of a subgroup of PCa to the advanced hormone-refractory stage [40,41]. Conversely, Bax effectively counteracts Bcl-2 function, promoting cellular apoptosis. Therefore, alteration of their ratios for example by inhibition of Bcl-2 and activation of Bax would lead to an apoptotic signal. We also analyzed the expression level of Bcl-XL in those cells. Unexpectedly, blocking EGFR signaling does not enhance gemcitabine-induced apoptosis of LNCaP C-81 cells despite the fact that Bax level is up-
regulated in those cells. The lack of enhancement of this combination treatment is at least in part due to a concomitant elevation of both Bcl-2 and Bcl-XL protein levels (Fig. 4B, lane #6), which compromises the Bax activity induced by gemcitabine. Conversely, AG825 can enhance gemcitabine-induced growth suppression on androgen-independent LNCaP C-81 cells in a steroid-reduced condition, which is at least in part due to the inhibition of Bcl-2 and Bcl-XL and concurrently the elevation of Bax protein (Fig. 3). Our data reveal that combination treatments could achieve growth suppression at lower concentrations than single agents alone (Fig. 2, lane #8 vs. Fig. 1). Our data further suggest that the sequential administration of gemcitabine and AG825 to patients could generate much more pronounced growth suppression than simultaneous administration of both agents (Fig. 2, lane #9). For its potential clinical applications, further studies in sequential dosing regimens of traditional anti-tumor agents and signal transduction inhibitors are needed. Additionally, studies could also target the expression of various apoptotic proteins to shift the ratio by enhancing pro-apoptotic over anti-apoptotic proteins to favor cell death.

Collectively, our data clearly show that ErbB-2 inhibition could enhance the gemcitabine-induced apoptosis, despite that several clinical evaluations show little advantage of either agent in the monotherapy setting [32]. The data further highlight the important role of ErbB-2 protein involvement in PCa progression, leading to hormone-refractory tumors. The results may then serve as a platform for the future development of effective therapeutic approaches to advanced PCa, particularly in the post-docetaxel patient for whom no standard-of-care exists. Further studies should address whether gemcitabine plus ErbB-2 inhibitor together with hormonal ablation therapy can delay the development of the androgen-independent phenotype and improve patient survival.

Acknowledgments
